Supporting Information

ABSTRACT: Symmetric sodium-ion batteries (SIBs) are considered as promising candidates for large-scale energy storage owing to the simplified manufacture and wide abundance of sodium resources. However, most symmetric SIBs suffer from suppressed energy density. Here, a superior congenic Na$_4$V$_2$(PO$_4$)$_3$ anode is synthesized via electrochemical preintercalation, and a high energy density symmetric SIB (Na$_4$V$_2$(PO$_4$)$_3$ as a cathode and Na$_3$V$_2$(PO$_4$)$_3$ as an anode) based on the deepened redox couple of V$^{4+}$/V$^{2+}$ is built for the first time. When measured in half cell, both electrodes show stabilized electrochemical performance (over 3000 cycles). The symmetric SIBs exhibit an output voltage of 3.0 V and a cell-level energy density of 138 W h kg$^{-1}$. Furthermore, the sodium storage mechanism under the expanded measurement range of 0.01–3.9 V is disclosed through an in situ X-ray diffraction technique.

KEYWORDS: sodium-ion battery, symmetric cell, 3.0 V, high energy density, Na$_4$V$_2$(PO$_4$)$_3$

INTRODUCTION

With the continuous depletion of fossil energy, the whole worldwide energy demand could be provided by renewable energy sources in the near future, such as solar, wind, and tide. Nevertheless, this green energy cannot be sufficiently used without proper storage. For large-scale energy storage applications, the most important objective is achieving the superior performance, security, and acceptable cost. As the most likely option in the field of large-scale electrochemical energy storage systems, sodium-ion batteries (SIBs) receive great attention because of the wide abundance and low cost of sodium resources, although their energy density is usually lower than that of lithium-ion batteries. Generally, symmetric systems have simplified manufacture and better compatibility compared with asymmetric systems, which can make the symmetric SIBs more capable in the matter of cost advantages for large-scale energy storage systems. In addition, security in large-scale applications is vital. Among the current electrode materials, Na superionic conductor (NASICON)-type materials are considered as one of the safest electrode materials because of their intercalation reaction and great structural stability. To sum up, considering the security and cost performance, symmetric SIBs with NASICON-type electrodes are considered as promising candidates for large-scale energy storage.

However, a lot of current efforts related to SIBs directed at large-scale applications have used the too complicated process for good performance, and their costs are far from meeting the need of large-scale manufactures. On the other hand, symmetric SIBs suffer from suppressed energy density owing to their low chemical potential, which immensely limited their applications. Thus, developing a high-energy NASICON-related symmetric SIBs with an inexpensive method could be a promising solution.

As the typical representative of NASICON-type materials, Na$_3$V$_2$(PO$_4$)$_3$ (NVP) has been greatly investigated for the symmetric SIB owing to its natural multistep redox reaction. Its unique structure provides a three-dimensional framework that is known for facile Na$^+$ ion migration. Taking advantage of the voltage difference between the two plateaus at around 3.3 and 1.6 V, Yamaki and co-workers first reported NVP-based symmetric SIBs in 2010. Afterward, Passerini et al. and Yu et al. introduced symmetric SIBs based on NVP bipolar electrodes with modified processes, delivering an output voltage of 1.7 V and connected...
Herein, we propose a high-performance SIB by using Na4V2(PO4)3 as a cathode and Na4V2(PO4)3 as an anode for the first time. The monocristalline NVP with carbon decoration (NVP/C) is synthesized as the target material. The congenetic Na4V2(PO4)3 anode is obtained through the preintercalation method. Both electrodes exhibit the outstanding cycling stability and rate performance when utilized as a cathode or an anode for SIBs. The symmetric SIBs based on the above redesign are fabricated for the first time. The monocrystalline NVP has a NASICON framework of the space group, JCPDS card no. 00-053-0018, corresponding well with the previously reported literature.33–35 This NVP has a NASICON framework of the \([\text{PO}_4]^{2−}\) tetrahedral units sharing corners with the \([\text{VO}_6]^{2+}\) octahedron units; the sodium atoms are located in the voids of the framework (Figure S1).24 The peak intensity of the XRD pattern of the framework (Figure S1).24 The peak intensity of the XRD pattern of the framework is determined to be 0.105°.

**Characterization.** The morphology was characterized by using a field emission scanning electron microscopy (SEM, JEOL JSM-7100F) at an acceleration voltage of 15 kV. The crystal structure was performed using a D8 ADVANCE X-ray diffractometer (Cu Ka radiation). The transmission electron microscopy (TEM) images and the selected-area electron diffraction (SAED) patterns were collected using a TEM (Titan G2 60-300, FEI). Raman spectra were obtained using a Renishaw INVia micro-Raman spectroscopy system. The pore structure and surface area were measured using a Tristar II 3020 instrument by nitrogen adsorption at 77 K. Carbon content analysis was determined by a Vario EL cube CHNSO elemental analyzer.

**Electrochemical Measurements.** The electrochemical performances were evaluated by assembling 2016 coin cells in a glovebox filled with argon gas. The electrodes were made by mixing active materials acetylene black and polyvinylidene with a mass ratio of 1:1, and N-methylpyrrolidone as a solvent. Then, the slurry was spread onto an aluminum foil and dried at 70 °C for at least 10 h. The electrolyte was 1 M NaClO4 in ethyl carbonate and dimethyl carbonate with a mass ratio of 1:1, and 5% fluoroethylen carbonate was used as an additive. A Whatman glass microfiber filter (Grade GE/F) was used as the separator. The mass loadings of the active material were 1.8–2.5 and 1.5–2 mg cm−2 for the anode and the cathode, respectively. The symmetric battery system balance was achieved by controlling the electrode capacity ratio of anode and cathode to 1:2. The battery was aged for 6 h before testing to ensure infiltration of the electrolyte. The cell-level energy density was calculated based on the masses of the cathode and anode. The cyclic voltammetry (CV) curves were obtained with an electrochemical workstation (CHI1000D). Galvanostatic charge/discharge measurements were cycled at a multichannel battery testing system (LAND CT2001A). The electrochemical impedance spectroscopy (EIS) was performed by an electrochemical workstation (Autolab PGSTAT302N, frequency range: 0.1 to 105 Hz).

**RESULTS AND DISCUSSION**

The phase characterization of NVP/C was verified by using a powder XRD (Figure 1a). All diffraction peaks are fully consistent with the NVP (R3c space group, JCPDS card no. 00-053-0018), corresponding well with the previously reported literature.33–35 This NVP has a NASICON framework of the \([\text{PO}_4]^{2−}\) tetrahedral units sharing corners with the \([\text{VO}_6]^{2+}\) octahedron units; the sodium atoms are located in the voids/channels of the framework (Figure S1).24 The peak intensity of NVP/C-650 is lower than that of NVP/C-750 (Figure 1a). This result indicates that the crystallinity of NVP/C-650 is lower than that of NVP/C-750. Some diffraction peaks of impurity are observed in NVP/C-650 owing to high annealing temperature.25 The high-resolution TEM (HRTEM)
image shows the amorphous carbon layer of NVP/C, and the thickness of the carbon layer is around 5 nm (Figure 1b). The marked lattice fringe with a $d$-spacing of 0.44 nm corresponds to the $d$-spacing of (104) planes. The SAED patterns indicate a single crystallization character of NVP/C, which marks to the (300) and (113) planes (Figure 1c). The homogeneous distributions of Na, V, P, O, and C elements were confirmed through energy-dispersive spectrometry (EDS) element mapping (Figure S2). The carbon content of the NVP/C sample is 8%, which was determined by the CHNSO elemental analyzer.

Raman spectroscopy is a powerful technique to characterize the carbon phase of NVP/C. The spectrum (Figure S3) shows two characteristic bands located at 1343 cm$^{-1}$ (D-band) and 1597 cm$^{-1}$ (G-band). The spectral parameters are achieved by curve fitting in the Gaussian numerical simulation. The ratio of $I_D/I_G$ is calculated to be 3.02, which indicates that the carbon layer exists as amorphous carbon. The surface area and pore structure of NVP/C were measured by the nitrogen isothermal adsorption technique (Figure S4). The surface area of NVP/C is 54.2 m$^2$ g$^{-1}$, and the pore size distribution curve
Figure S4 inset) displays that the pore sizes are mainly below 25 nm. Prior to the measurement, the anode underwent an electrochemical route to form the sodiated phase (Na4V2(PO4)3) and the stable solid electrolyte interface (SEI) (Figure 1d). We employed a galvanostatic discharge/charge cycle with coin cell upon 1.2 V to achieve the electrochemical preintercalation (Figure S5), and Figure S6 indicates the formation of the SEI after the electrochemical measurement. In fact, the electrochemical preintercalation strategy presented here is a proper way to reveal the nature of the material. More easily scalable solvothermal routes for preintercalation may be more achievable in industry, which should be further developed.

The electrochemical performances of the prepared material as an anode or a cathode with coin cells for SIBs were checked in the voltage windows of 0.01−1.2 and 2.5−3.9 V, respectively. NVP/C-750 delivers the highest initial discharge capacities of 105 and 110 mA h g⁻¹ as an anode and a cathode, respectively (Figure 2a,b), compared to those of NVP/C-650 (75 and 88 mA h g⁻¹) and NVP/C-850 (82 and 97 mA h g⁻¹). This is owing to the low crystallinity of NVP/C-650 and the impurity of NVP/C-850, which lead to the instability of the crystal, especially during the mass of Na⁺ ion insertion. Two pairs of redox peaks at around 0.3 V (anode) and 3.3 V (cathode) are observed within CV curves (Figure 3a,b), corresponding to the redox couples of V³⁺/²⁺/V²⁺ and V⁴⁺/V³⁺, respectively. The long-term cycling stabilities of NVP/C-750 were tested with the galvanostatic charge−discharge measurement at 40 mA g⁻¹ (Figure 3c,d). The capacities of NVP/C-750 maintain 84 and 93 mA h g⁻¹ after 3000 cycles, corresponding to the capacity retention of 81 and 84% as an anode and a cathode, respectively. NVP/C also displays excellent rate performances (Figure 3e,f). When the current densities return to the beginning, the capacities can reach as high as the initial capacities. The reversible capacity of the Na4V2(PO4)3 anode reaches up to 210 mA h g⁻¹, which was revealed by the galvanostatic intermittent titration technique (GITT, Figure S7).

On the basis of above results, symmetric full cells were assembled by using NVP/C electrode materials. The schematic diagram of the symmetric full cell is proposed in Figure 4a. Na⁺ ions are extracted from Na3V2(PO4)3 to form NaV2(PO4)3, and Na⁺ ions inset in Na4V2(PO4)3 to form Na5V2(PO4)3. The reactions of the cathode (I) and anode (II) in the symmetric battery can be described as follows

\[
\text{Na}_4\text{V}_2\text{(PO}_4\text{)}_3 \leftrightarrow \text{Na}_5\text{V}_2\text{(PO}_4\text{)}_3 + 2\text{e}^- + 2\text{Na}^+ \quad (I)
\]

\[
\text{Na}_5\text{V}_2\text{(PO}_4\text{)}_3 + \text{e}^- + \text{Na}^+ \leftrightarrow \text{Na}_4\text{V}_2\text{(PO}_4\text{)}_3 \quad (II)
\]
The oxidation and reduction peaks (3.2 and 2.95 V, respectively) of V\textsuperscript{4+}/V\textsuperscript{2+} can be observed from the CV curves (Figure S10). The simulated charge–discharge curves are obtained from the difference of half cells, agreeing well with the experimental results (Figure 4b). The cell-level capacity of the full cell (based on the total mass of the cathode and anode active materials) can be determined from the standard relationship as follows\textsuperscript{44,45}

\[
C_{\text{full}} = \frac{1}{\frac{1}{C_a} + \frac{1}{C_c}} = \frac{C_a C_c}{C_a + C_c}
\]

where \(C_{\text{full}}, C_a\), and \(C_c\) is the specific capacities of the full cell, anode, and cathode, respectively. The resistance of the full cell was measured by the EIS (Figure 4c), the high-middle frequency semicircle stands for the charge-transfer resistance \(R_e\) between the electrodes and the electrolyte and the line in the low-frequency range represents the Warburg diffusion. On the basis of the fitted equivalent circuit, the \(R_e\) values of the full cell after 2, 20, and 100 cycles are 174, 210, and 224 \(\Omega\), respectively. The typical voltage profiles show that our full cells deliver an output voltage plateau of 3.0 V and a cell-level capacity of 46 mA h g\textsuperscript{-1} (Figure 4d). In contrast, the prototype traditional NVP-based symmetric battery delivers an output voltage of 1.7 V and a cell-level capacity of 36 mA h g\textsuperscript{-1}. Figure S11 shows that the obtained full cell is capable of lighting the light-emitting diode bulb. The capacity retention is 87\% after 100 cycles (Figure 4e). Because of the SEI building in advance, the initial Coulombic efficiency of the full cell can reach as high as 95\%. The rate performance of the full cell was also measured (Figure S12). When the current density reached to 160 mA g\textsuperscript{-1}, the cell-level capacity of 24 mA h g\textsuperscript{-1} was maintained. With the current density returned back to 40 mA g\textsuperscript{-1}, more than 40 mA h g\textsuperscript{-1} cell-level capacity could be recovered. The cell-level capacities, discharge voltages, and energy densities of recently published symmetric SIBs are presented in Figure 4f. To ensure that our comparisons are under the consistent standard, the cell-level capacity and energy density of recently published symmetric SIBs have been recalculated.\textsuperscript{46} It is clear that our work has a cell-level energy density of 138 W h kg\textsuperscript{-1}, which has a decent improvement compared to the previous symmetric SIBs.

To learn more about the electrochemical processes in real time, the in situ XRD technique has been utilized to investigate the sodium-ion storage mechanisms of NVP.\textsuperscript{52} The 2\(\theta\) was recorded from 28\(^\circ\) to 38\(^\circ\), a proper range that can reflect the structural transformation of NVP. At the beginning of the process, all diffraction peaks can be identified as Na\(_2\)V\(_2\)(PO\(_4\))\(_3\), with the NASICON structure. In Figure 5a, with the charging procedure, some new peaks appear and gradually strengthen. This process can be considered as the coexistence of two phase, corresponding to the voltage plateau. The diffraction peaks can be indexed to Na\(_2\)V\(_2\)(PO\(_4\))\(_3\) at the end of charging.\textsuperscript{73} Upon the discharge to 2.7 V, the XRD pattern of Na\(_2\)V\(_2\)(PO\(_4\))\(_3\), completely disappears, whereas those from Na\(_3\)V\(_2\)(PO\(_4\))\(_3\) are observed. The structure transforms back to the original NVP phase at the end of discharge. A similar behavior but with the opposite trend is observed when the electrode was tested at voltage ranges of 0.01–3.0 V (Figure 5b). Upon the discharge to 1.2 V, diffraction peaks of (024) and (300) shift to smaller angles, which indicating the Na\(^+\) ions insertion related to the d-space increasing. No new peaks appear or disappear, which cannot indicate the coexistence of two phases. With further discharge process, insertion of Na\(^+\) ions induces the disappearance of peaks of (024) and (116) and some new peaks appear. This process can also be considered as the coexistence of two phase, and the diffraction peaks can be indexed to Na\(_3\)V\(_2\)(PO\(_4\))\(_3\).\textsuperscript{51} Figure 5c,d shows the schematic illustration of the unit cells. As the cathode, there are three sodium atoms per NVP unit and two removable atoms of them located at the 18e site, occupying 2/3 of the vacancy, corresponding to the transformation of Na\(_2\)V\(_2\)(PO\(_4\))\(_3\)/Na\(_3\)V\(_2\)(PO\(_4\))\(_3\) phases.\textsuperscript{53} The third atom occupies the 6b site, which cannot be extracted from the structure. As the anode, there are five sodium atoms per unit and only one of them at the 6a site could be extracted, corresponding to the transformation of Na\(_2\)V\(_2\)(PO\(_4\))\(_3)/Na\(_3\)V\(_2\)(PO\(_4\))\(_3\) phases.\textsuperscript{53}

### CONCLUSIONS

In summary, the congeneric Na\(_2\)V\(_2\)(PO\(_4\))\(_3\) anode was obtained by using the preintercalation method, and the high-performance symmetric SIBs were assembled by using Na\(_2\)V\(_2\)(PO\(_4\))\(_3\) as a cathode and Na\(_3\)V\(_2\)(PO\(_4\))\(_3\) as an anode for the first time. The electrodes exhibit a stabilized electrochemical performance (over 3000 cycles) when utilized as an anode or a cathode. The full cell shows a higher output voltage of 3.0 V and a higher energy density of 138 W h kg\textsuperscript{-1} than the previous symmetric SIBs of 1.7 V and ~70 W h kg\textsuperscript{-1}. These results introduce a kind of effective and feasible way to improve the electrochemical performance of oxidation–reduction cells. We employed the in situ XRD technique to disclose the sodium storage mechanism. This work makes the symmetric SIBs more capable in the field of large-scale energy storage applications.
